Introduction

Terrace deposits with material sources in mountain belts represent important archives of past environmental and tectonic changes. These sediments can record modifications in paleo-water discharge, which is a proxy for precipitation rates and climate (Sylvia and Galloway, 2006; D’Arcy et al., 2017; Litty et al., 2017). They can also record the response to earthquake induced landslides (Dadson et al., 2001; McPhillips et al., 2014), and changes in tectonic uplift rates. The reconstruction of the timing and the shape of alluvial deposits, paired with information about the provenance of the material bear important information when the scope lies in the detection of specific climate or seismic events as driving forces on erosion and sediment fluxes. This has particularly been the case for the Central Andes (Strecker et al., 2007), where previous studies have identified a strong environmental control on erosion (Reber et al., 2017), sediment transfer, landscape form (Montgomery et al., 2001; Trauerstein et al., 2013) and the construction of terrace sequences particularly in the Andes (Steffen et al., 2009; Bekaddour et al., 2014; Savi et al., 2016; Tofelde et al., 2017). In this context, it has been proposed that variations in precipitation rates and patterns have led to remarkable lake-level variations on the Altiplano (Fritz et al., 2004). These climate changes, with orbital frequencies of 100 ka, 40 ka and 20 ka, were also considered to have controlled pulses of erosion and sediment discharge by modulating the fluvial runoff on the western Andean margin (Steffen et al., 2009; Bekaddour et al., 2014; Veit et al., 2016; Litty et al., 2017), which in turn, has been interpreted as being the main factor controlling the formation of cut-and-fill terrace systems in this region (Norton et al., 2016). Accordingly, the Andean mountain range could be perceived as an ideal laboratory for exploring a climate forcing not only on surface mass fluxes, but also on the tectonic history of this mountain belt through a positive feedback to climate change (Norton and Schlunegger, 2011). However, the interpretation of climate, and more specifically of an orbital control on surface mass flux
and the construction of terrace sequences is based on three archives only that are sparkled along the Peruvian coast over a distance of c. 1000 km: Pativilca at 10°42'S (Trauerstein et al., 2014; Litty et al., 2018); the Pisco valley at 13°42'S (Steffen et al., 2009) and the Majes valley at 16°13'S latitudes (Steffen et al., 2010). We complement this dataset through analysis of the fan deposits, situated at Lima, 12°03'S.

We explore the hypothesis whether the construction of terrace deposits along the Peruvian coastal margin records a possible orbital control on the erosional history of the adjacent Andean mountain belt. We complement an already existing database and focus on the terrace deposits at Lima, where we explore the geological history of these deposits and underlying controls with dating and provenance tracing techniques, and through the estimation of paleo-denudation rates. As a first effort, we date the deposits using isochron burial dating technologies thereby using in situ cosmogenic 10Be and 26Al. We use these age constraints to explore possible correlations with any known period of enhanced precipitation, interglacial stages or tectonic activity in an effort to distinguish between the different possible controlling mechanisms leading to sediment accumulation. Second, the paleo-basin-wide denudation rates, recorded at different levels of the sedimentary sequence, will be determined using concentrations of in situ cosmogenic 10Be preserved in these sediments. This will allow us to determine if the sediment accumulation period also records a pulse of erosion. Finally, we will determine the provenance of the fine-grained sediments embedded in the conglomerate through detrital zircon U/Pb in situ dating techniques, which will constrain the location where the erosion of the Lima Conglomerate material occurred. This new information will support the emerging picture of an orbital control on erosion, sediment transport and the construction of terraces in the Andes.

**Regional Setting**

**Chronology and sedimentology of the Lima Conglomerate**

The Lima Conglomerate (Figures 1 and 2; Karakouzian et al., 1996) is an alluvial fan made up of coarse-grained massicebedded conglomerates with minor interbedded sandstones and mudstones. The best exposures can be found along the Pacific coast near Miraflores, a southern district of the city of Lima. There, this unit is made up of an up to 80-m-thick stack of poorly sorted, clast-supported conglomerates with a coarse-grained sandy matrix. The fan stretches along the Pacific coast over a distance of 15 km, and it has a convex-up, fan-shaped asymmetric geometry (Figure 1). This suggests that the Lima Conglomerate forms one single fan. The sediments were deposited by the Chillon and Rimac Rivers that have their origins in the Andes c. 120 km farther upstream at an elevation of c. 4800 m a.s.l. (Figure 1).

Karakouzian et al. (1996) suggested a Pleistocene age for these deposits, without providing constraints on their age assignment. Le Roux et al. (2000) proposed a middle Pleistocene age on the grounds of geomorphologic, stratigraphic and soil-stratigraphic evidence. The only fossiliferous evidence to infer an age, at least to our knowledge, is from the top of this formation, where a molar tooth of Equus curvidens Owen, which is of Pleistocene age, was recovered (Lisson, 1907). However, in spite of good outcrops along the coast no results of any dating campaigns have ever been published. This paper thus reports the first numerical age of the Lima Conglomerate deposits and aims at unravelling the controls on the deposition of the fan delta.

The clasts embedded within the conglomerates are subrounded and sometimes imbricated, but the sedimentary fabrics are predominantly massive. The contact between the conglomerate suite and the underlying basement is situated below sea level and cannot be constrained. The sedimentological architecture of the exposed succession is characterized by an amalgamation of several-meter-thick units. Each of them has an erosive basal contact indicating deposition after rapid channel flow, as noted by Le Roux et al. (2000). The same authors found that cross-beds with meter-high shallow-dipping foresets, or alternatively troughs with several-meters-wide diameters, alternate with massive-bedded structures that appear as the dominant facies. Sandstones within the conglomerate are mostly lenticular, overlying erosional surfaces. Most of the sandstones are trough cross-laminated, although antidune cross-lamination and low-angle tabular cross-lamination were also observed (Le Roux et al., 2000). Sandstone beds or lenses commonly fine upward into siltstone and mudstone, suggesting waning currents after high-discharge episodes (Le Roux et al., 2000). These facies-associations suggest the supply, transport and deposition of coarse-grained bedload by braided streams (Miall, 1985) that formed an alluvial fan where the frontal part has now been eroded subsequent to deposition. In these environments where braiding occurs, cross-bedded conglomerates on top of an erosive base point to the occurrence of gravely bedforms in shallow channels, while massive-bedded conglomerates with sandstone lenses were most likely formed on top of longitudinal bars, where sand becomes deposited during waning floods in a high energy environment of rapidly shifting braided channels (Miall, 1985; Le Roux et al., 2000). There is a complete absence of any signs of marine influence (e.g. beach imbrication,
and marine fossils) in the exposed part of the succession, which suggests that the conglomerates have not been reworked by waves (Le Roux et al., 2000). Mapping in the field discloses a lens-shaped cross-sectional geometry for the top surface of the Lima Conglomerate, which stretches over a distance >15 km parallel to the Pacific coast (Figure 1). The surface of the Lima unit thus displays all characteristics of an alluvial fan: it is situated next to an ocean, the surface is convex-up in a section perpendicular to the flow and the surface is highest along the fan axis (Figure 1).

Bedrock geology of the source area

The clasts encountered in the Lima Conglomerate reflect the composition of the Andean Cordillera and mainly comprise diorites, granodiorites, granites and gabbros derived from the Late Cretaceous Coastal Batholith. Mesozoic and Cenozoic volcanic as well as pyroclastic constituents also occur in the clast suite of the conglomerate (LeRoux et al., 2000; Figure 1). In the area surrounding the Lima drainage basin, the chronology of the intrusion of the batholith was established in detail by Wilson (1975), who identified three intrusive episodes separated by periods of relative magmatic quiescence. These include: the emplacement of the gabbroic, meladioritic, and tonalitic plutons c. 105–85 Ma ago; the intrusion of the granodioritic plutons c. 75–56 Ma ago; and the formation of the granites and monzogranites c. 39–33 Ma ago.

Climate

The precipitation pattern of the western Peruvian Andes is strongly influenced by the Andean mountain range, which acts as a major topographic barrier to atmospheric circulation. The precipitation pattern is also related to the position of the Intertropical Convergence Zone (ITCZ) associated with orographic effects on the eastern side of the Andes (Bookhagen and Strecker, 2008). The climate is characterized by wet phases and strong precipitation rates during austral summer, particularly on the Altiplano, and by dry persistent westerly winds with almost no precipitation during austral winter. During this period, the western side of the Peruvian Andes experiences zero precipitation. As a result, precipitation rates in the Rio Rimac and Chillon basins decrease from east to west, with an annual precipitation rate up to 400 mm on the Altiplano down to c. 0 mm per year in the coastal area.

On orbital time scales, the position of the ITCZ has shifted in response to larger heat contrasts between the Northern and Southern Hemispheres, which has been related to the effects of shifts in the Earth’s orbital parameters (Strecker et al., 2007). The results are stronger upper air easterlies and more precipitation on the Altiplano during time intervals of larger insolation on the Altiplano (Garreaud et al., 2003; Strecker et al., 2007). Variations in precipitation rates and patterns led to remarkable lake-level variations on the Altiplano as recorded by lake level highstands on the plateau (Fritz et al., 2004). These shifts in precipitation rates were also considered to have resulted in changes in the loci of erosion as provenance tracing techniques have shown (Litty et al., 2017), and in changes in erosion rates as suggested by concentrations of $^{10}$Be measured in terrace material along the Pisco valley (Bekaddour et al., 2014).

Sampling sites

Three levels, on a vertical transect, on the coastal cliff of the Lima Conglomerate in the district of Miraflores, have been sampled for $^{10}$Be/$^{26}$Al isochron burial dating, paleo-erosion rates and provenance tracing purposes (Figure 2; Table I). This transect has been selected because of its accessibility thanks to the presence of stairs from the bottom of the cliff to the top in Miraflores (Figure 2(B)). In particular, we collected samples from three levels including site LIM-IS3, which is the lowermost level of the deposits (Figure 2(C) and 2(D)), site LIM-IS2 representing an intermediate level (24 m above site LIM-IS3; Figure 2(E) and 2(F)); and site LIM-IS1 corresponding to the

![Figure 2](https://example.com/figure2.png)
topmost level of the sequence (33 m above site LIM-IS3; Figure 2(G) and 2(H)). At LIM-IS3, three quartz bearing pebbles have been collected, while six quartz bearing clasts were taken at site LIM-IS2 and four quartz rich pebbles have been used for the measurement of the isochron at LIM-IS1. In addition, three sand samples, one at each level (sand samples LIM-PE3, LIM-PE2 and LIM-PE1 from base to top), have been collected from the matrix of the conglomerates for calculations of the paleo-basin-wide denudation rates. Finally, the same sand samples have been used to infer the provenance of the fine-grained sediments.

Methods

Isochron burial dating

Over the past 25 years, cosmogenic nuclides have become an essential tool in Quaternary geochronology (Gosse and Phillips, 2001; Granger, 2006; Schaller et al., 2016). The cosmogenic $^{26}\text{Al}-^{10}\text{Be}$ isochron burial dating method (Balco and Rovey, 2008; Erlanger et al., 2012; Akçar et al., 2017) has been employed to determine burial ages and to establish the timing of deposition of the alluvial material. This dating technique is based on the difference in half-lives of $^{10}\text{Be}$ (1.387 Ma; Korschinek et al., 2010 and Chmeleff et al., 2010) and $^{26}\text{Al}$ (0.705 Ma; Norris et al., 1983). We collected samples from the same stratigraphic level, thereby assuming that they were deposited at nearly the same time. No tectonic offsets are found in the field, which suggests that the deposits have not been deformed or faulted since the time of their deposition. Accordingly, a horizontal line represents the same stratigraphic level. This method works if the collected material has different inherited nuclide concentrations but the same post-burial production history (Balco and Rovey, 2008; Darling et al., 2012; Erlanger et al., 2012; Balco et al., 2013; Çiner et al., 2015; Bender et al., 2016; Akçar et al., 2017). When the measured $^{26}\text{Al}$ concentrations are plotted against $^{10}\text{Be}$ concentrations, they should fall on a line, referred to as the isochron (Balco et al., 2008; Erlanger et al., 2012). The slope of the regression line is used to determine the $^{26}\text{Al}/^{10}\text{Be}$ ratio at the time of burial and thus the depositional age (for further details see Balco and Rovey, 2008, Darling et al., 2012, Balco et al., 2013 and Çiner et al., 2015).

The $^{26}\text{Al}-^{10}\text{Be}$ isochron burial method provides several key advantages for dating conglomerate deposits in general and the Lima Conglomerate in particular. First, the isochron burial method works well for sediments that are between ~0.1 and ~5.0 Ma old (Granger, 2006). Given that former studies have suggested a Pleistocene age for this unit (Lisson, 1907; Karakouzian et al., 1996), we expected the age of the accumulation of the Lima Conglomerate material to fall within this range.

The collected samples were processed in the Surface Exposure Laboratory of the Institute of Geological Sciences at the University of Bern following the lab protocol described in Akçar et al. (2012). Cosmogenic $^{10}\text{Be}$ and $^{26}\text{Al}$ were extracted according to Akçar et al. (2012) for accelerator mass spectrometer measurements (AMS) at the ETH Zurich (Kubik and Christl, 2010; Christl et al., 2013). Inductively coupled plasma optical emission spectrometry (ICP-OES) at the Department of Chemistry and Biochemistry of the University of Bern was used to determine the total Al and native $^{9}\text{Be}$ concentrations of the samples. The $^{10}\text{Be}^{9}\text{Be}$ and $^{26}\text{Al}^{27}\text{Al}$ AMS measurements were then performed at the tandem facility at the ETH Zurich (Christl et al., 2013). A long-term weighted average $^{10}\text{Be}^{9}\text{Be}$ ratio of $(2.51 \pm 0.53) \times 10^{-15}$ was used for full process blank correction. To calculate the isochron burial age, a $^{26}\text{Al}^{10}\text{Be}$ surface production ratio of 6.75 has been used. A production rate of cosmogenic $^{10}\text{Be}$ at the
surface at sea level–high altitude (SLHL) of 4.00 ± 0.32 atoms g⁻¹ SiO₂⁻¹ a⁻¹ has been applied (Borchers et al., 2016). The altitude and latitude scaling of the surface production rate was calculated following Braucher et al. (2010) following Petrus and Kamber (2012). Visual interpretation of the samples was conducted at an A beam current, ~10 mm² chamber pressure, to examine the possible presence of inclusions of other minerals that can influence the U–Pb isotopic results. The most suitable locations of the spots for U–Pb analyses were then selected on the grain rims where neither inclusions nor strong chemical zoning were found. U/Pb measurements were conducted at the Institute of Geological Sciences of the University of Bern using a GeoLas-Pro 193 nm ArF Excimer laser system (Lambda Physik) combined with an Elan quadrupole mass spectrometer. Detailed analytical protocols are reported in Kunz et al. (2017). Ablation was conducted at an energy density of 2.5 μm² with a repetition rate of 9 Hz using a spot size of 24 μm. Zircon standard GJ-1 (Jackson et al., 2004), and glass reference material NIST SRM 612 was used for the quantification of isotopic and element concentrations. Accuracy and long-term reproducibility was monitored using zircon standard Pleißovice (337.13 ± 0.37 Ma; Sláma et al., 2008). Data reduction for U/Pb-dating was done using the software Iolite 2.5 (Paton et al., 2010) following Petrus and Kamber (2012). Visual age data reduction schemes and error propagation methods are built into U–Pb Geochronology Iolite Software. Only grains with concordant U–Pb ages have been used. One of the main problems in detrital zircon geochronology is to determine the minimum number of grains to be analysed to ensure that all populations are detected. In addition, the geological information that can be extracted from a set of age data on detrital zircons is critically dependent on the number of analysed grains (Vermeech, 2004). Indeed, a distribution with one single age cluster is unlikely to occur in natural sediments. In a more realistic scenario, sediments may contain several age populations, each of which has a non-uniform age distribution. Previous studies of the provenance of sediments that used U–Pb dating of detrital zircon (Morton et al., 1996) have shown that precise and accurate U–Pb ages of 80 to 100 zircon grains in each sample are needed for a reliable identification of the major sedimentary sources (Dodson et al., 1988). However, Andersen (2005) suggested that the random fraction should comprise 35–70 grains or more, depending on the complexity of the age-pattern of a specific sample. Andersen (2005) suggested that the relative error in the population size decreases with increasing number of analyses, but that this decrease occurs only slowly for small populations. Here, 58 and 63 zircons have been dated for the modern samples LIM-ME and LIM-ME2 respectively and 107, 44 and 70 zircons have been dated for the terrace samples LIM-PE1, LIM-PE2 and LIM-PE3 respectively.

Results

Isochron burial dating

AMS-measured ⁰⁸⁰Be/⁰²⁶Al and ⁰²⁶Al/⁰²⁷Al ratios (with uncertainties) as well as calculated ⁰⁸⁰Be, ⁰²⁶Al concentrations and
The $^{10}$Be concentrations of the four samples of the upper part of the sequence (LIM-IS1) vary from $1.4 \times 10^3$ atoms g$^{-1}$ (LIM-IS1-4) to $170 \times 10^3$ atoms g$^{-1}$ (LIM-IS1-1) and the $^{26}$Al concentrations from $8.2 \times 10^3$ atoms g$^{-1}$ to $740 \times 10^3$ atoms g$^{-1}$ for the same samples, respectively (Table II). The $^{26}$Al/$^{10}$Be ratios vary from $4.37 \pm 1.79$ (LIM-IS1-1) to $6.74 \pm 0.93$ (LIM-IS1-8). The $^{10}$Be concentrations of the six samples of the middle part of the sequence (LIM-IS2) span the range from $1.0 \times 10^3$ atoms g$^{-1}$ (LIM-IS2-6) to $37 \times 10^3$ atoms g$^{-1}$ (LIM-IS2-9) and the $^{26}$Al concentrations from $7.8 \times 10^3$ atoms g$^{-1}$ (LIM-IS2-4) to $445 \times 10^3$ atoms g$^{-1}$ (LIM-IS2-9). The $^{26}$Al/$^{10}$Be ratios range from $8.09 \pm 0.87$ to $33.5 \pm 12$. Finally, the $^{10}$Be concentrations of the three samples of the bottom part of the sequence (LIM-IS3) vary from $1.3 \times 10^3$ atoms g$^{-1}$ (LIM-IS3-5) to $121 \times 10^3$ atoms g$^{-1}$ and the $^{26}$Al concentrations from $1.07 \times 10^3$ atoms g$^{-1}$ to $121 \times 10^3$ atoms g$^{-1}$ for the same samples, respectively. The $^{26}$Al/$^{10}$Be ratios range from $5.71 \pm 0.19$ to $8.18 \pm 0.85$. The measured $^{26}$Al concentrations are plotted versus $^{10}$Be concentrations including $1\sigma$ uncertainties (Figure 3). The results from the isochron burial dating yield a burial age of $500 \pm 70$ ka for the bottom part of the sequence and a burial
Paleo-erosion rates

The in situ $^{10}$Be analytical data together with the inferred paleo-catchment-wide denudation rates obtained for the deposits are presented in Table III. We have used the AMS-measured concentrations that were corrected for the production of the post-depositional nuclide concentrations at sample depth $z$ and atom loss due to radioactive decay since the deposition of the sediments (Table III; since $c. 500$ ka). For the sample LIM-IS2, no ages could be calculated through isochron burial dating. However, considering that the sample is located stratigraphically between the sites LIM-PE3 and LIM-PE1, the depositional age of the sediments must also correspond to $c. 500$ ka. We thus used this age to correct the cosmogenic concentration for atom loss due to radioactive decay since the time of the deposition. Accordingly, this results in the following $^{10}$Be concentrations at the time of deposition: $96492 \pm 1927$ atoms g$^{-1}$ for LIM-PE1, $137436 \pm 4894$ atoms g$^{-1}$ for LIM-PE2 and $155918 \pm 6107$ atoms g$^{-1}$ for LIM-PE3. As a result of this, the calculated paleo-catchment-wide denudation rates are $105 \pm 10$ mm ka$^{-1}$ (LIM-PE3), $119 \pm 11$ mm ka$^{-1}$ (LIM-PE2) and $169 \pm 14$ mm ka$^{-1}$ (LIM-PE1) for the bottom, the middle and the top levels of the studied deposits, respectively (Table III and Figure 5).

Sediment provenance through U/Pb detrital zircon dating

For the Lima drainage basin, Litty et al. (2017) have shown that in situ U/Pb zircon ages of modern sediments at the coast yield two distinct age populations (20 and 60 Ma; Figures 1 and 6). A modern sample farther upstream close to the inland limit of the coastal batholith (Figure 1) yields a single main zircon-age population centred on $c. 20$ Ma (Figure 6; Litty et al., 2017). The sample LIM-PE1 used in the analysis by Litty et al. (2017) has been complemented to obtain a total of $107$ dated grains (60 additional dated grains). Additionally, 44 and 70 zircon grains have been dated for sites LIM-PE2 and LIM-PE3 respectively (Figure 6). These samples record three zircon populations ranging between 8 and 16 Ma whereas sample LIM-PE1 shows only two populations in this age range. Age patterns of the three samples yield two large populations around 18 and 20 Ma and four zircon populations ranging between 24 and 36 Ma. Then, the results of samples LIM-PE2 and LIM-PE1 return two populations around 44 Ma whereas the sample LIM-PE3 returns only one zircon population at 44 Ma. The main differences between the samples are observed in the zircon populations older than 44 Ma. The samples LIM-PE2 and LIM-PE3 chronicle a population around 64 Ma that is not observed in sample LIM-PE1. In addition, the sample LIM-PE3 exhibits indistinct age populations ranging between 72 and 80 Ma. Sample LIM-PE2 shows one zircon population at 68 Ma that is hidden in the 64 Ma cluster, and one population at $c. 81$ Ma. Results of the sample LIM-PE1 yield one population at 57 Ma that is not observed in the two other samples. Additionally, the sample records two populations at $c. 68$ and at $c. 72$ Ma. Finally, the three samples show one zircon population at $c. 85$ Ma.

Discussion

The results of the isochron burial dating imply that the accumulation of the Lima Conglomerate occurred around $500$ ka ago. The two sites (lowermost and topmost sites), separated by $c. 30$ m in the vertical section from each other, record identical ages within errors. These results imply that the sediment accumulated relatively fast and within a short time interval. This period of fast sediment accumulation was superseded by a phase of erosion and recycling of the previously deposited material through the combined effect of fluvial and wave activities, which resulted in formation of the spectacular cliff at Lima. We have no age constraints to infer the time when the phase of sediment accumulation ended, and when waves and streams started to recycle and erode the conglomerates. Likewise, we

Figure 5. Erosion rate during the time of sediment accumulation versus the altitude of the sampling site. This shows an increase of the paleo-erosion rate with the altitude.
lack age brackets to date the commencement of the conglomerate construction at Lima. In the following section, we discuss possible controls on the sediment accumulation of the Lima Conglomerate (uplift, eustatic sea level rise, climate-driven erosional pulse) thereby considering the sedimentation ages, the recorded increase in denudation rates and the provenance signal.

Fan progradation and sediment accumulation in response to an erosional pulse

We interpret the construction of the Lima conglomerate as a response to a wave of erosion in the hinterland, thereby resulting in a sediment pulse, the progradation of the fan and the accumulation of coarse-grained material. In this context, the evidence for a 60% increase in \(^{10}\text{Be}\)-based denudation rates becomes important.

The modern erosion rates that have been calculated in the lowermost reaches of the entire western Peruvian Andes (Reber et al., 2017) range from 9 mm ka\(^{-1}\) to 190 mm ka\(^{-1}\) with an average value of c. 38 mm ka\(^{-1}\). The observed denudation rates increase either with mean basin slope angles or with mean annual water discharge suggesting a strong environmental control and no tectonic driving force on the denudation on a millennial time scale. For the modern Rio Rimac, Reber et al. (2017) reported a basin-averaged denudation rate of c. 197.6 ± 43.3 mm ka\(^{-1}\), which is higher than the rates calculated for the Lima Conglomerate deposits (104.6 ± 9.3 mm ka\(^{-1}\) to 169.6 ± 13.9 mm ka\(^{-1}\) from base to top). However, the Rio Rimac sample is located farther upstream. Most important in this context, however, is the rapid 60% increase of the inferred paleo-wide denudation rates from 105 to 165 mm ka\(^{-1}\) within a very short timespan. We use this short-term increase to infer the occurrence of an erosional pulse in the hinterland, which most likely resulted in the accumulation and the progradation of the Lima Conglomerate alluvial fan. We thus consider that this inferred erosional pulse resulted in a relatively high sediment flux to the coast, causing the fan of the Rimac and Chillon rivers to prograde and the Lima Conglomerates to accumulate. Once the hillslopes in the upstream catchment have been liberated from the regolith cover, sediment supply to the trunk stream decreased with the result that sediment flux in the trunk streams could have dropped below the transport capacity. This could have initiated the phase of erosion and recycling of previously deposited material. A similar scenario has been proposed for the construction of the terrace deposits in the Pisco valley about 200 km farther south (Steffen et al., 2009) where ages of the terrace deposits are 40 ka and 20 ka, and in the Pativilca valley 200 km farther north where multiple sets of conglomerate units yielded OSL ages of c. 20 and 100 ka (Trauerstein et al., 2014), and cosmo-based depth-profile ages of c. 200 ka and c. 1.2 Ma (Litty et al., 2018), albeit with large errors. Finally, ages of c. 20 ka, 40–60 ka and 100 ka have also been reported for fan systems and terrace deposits in the Majes valley c. 650 km farther southeast. At Pisco, the accumulation and construction of valley fill conglomerates occurred during a period of fast erosion, as \(^{10}\text{Be}\)-based paleo-denudation rates imply (Bekaddour et al., 2014). In the same sense, Norton et al. (2016) proposed that the deposition of fluvial conglomerates on valley floors was most likely associated with the occurrence of an erosional pulse on the bordering hillslopes, while the subsequent downcutting occurred as the sediment reservoirs on the bordering hillslopes became depleted. Following these lines, we propose that this inferred pulse of erosion could have been responsible for the relatively fast sediment aggradation and for the construction of the Lima Conglomerate.

The samples LIM-PE1, LIM-PE2 and LIM-PE3 show similarities in their zircon population and exhibit a more complex signal with a larger number of age populations compared with the modern river samples (Figure 6). The similarities observed between the three sand samples indicate that they share nearly identical sediments sources. The sediments were mainly eroded from the catchment of the Rio Rimac with some material supplied by the Rio Chillon. For example, the distinct peak at 20 Ma, which is found in the three samples, has been identified as representing zircon crystals derived from the upper part of the Rio Rimac catchment (Liity et al., 2017). The 72 Ma peak in the age pattern, which is also observed in the three samples, suggests that the material was most likely supplied from the coastal batholith in the Rio Chillon catchment (Mukasa, 1986). Additionally, the broader range of zircon ages in the three terrace samples indicates that the sediment of the matrix has been eroded from a broader area in comparison with the modern river sediments. Accordingly, these results are in line with those from our previous study (Litty et al., 2017). This implies that the modern sediment sources are mainly located along the steep middle reaches of the rivers, whereas during the period of the deposition of the alluvial fan material, sources were additionally located in the low-relief headwaters of these catchments (Litty et al., 2017). Note that the sample LIM-PE1 shows differences in its provenance compared with the two other samples (Figure 6). Because this shift in the erosional loci was coincident with higher erosion rates compared with the two other samples, we tentatively interpret that this change in the erosion rate might have affected the provenance signal.

Discarded possible controls on the inferred sediment pulses

A first explanation includes the scenario where a possible rainfall-driven (or alternatively an earthquake triggered) landslide might have dammed a lake within the upstream valley. Breaching of this dam might have initiated a wave of sediment flux (Korup et al., 2010), thereby causing the alluvial fan to prograde and gravels to accumulate. Although this is a valuable interpretation, we do not favour this scenario because the recorded change in the cosmogenic signal requires an increase in erosion rates over an area that is much larger than the scale of individual or even multiple landslides and/or rock avalanches (von Blanckenburg, 2006). Indeed, landsliding, lake damming and breaching, and the resulting sediment pulse is unlikely to be recorded by a change in the concentrations of cosmogenic nuclides provided that these processes are widespread and occur over a broader time scale, as generic models of the dependency of \(^{10}\text{Be}\) concentrations in stream sediments and landsliding in the upstream basin suggest (Niemi et al., 2005). The decrease in \(^{10}\text{Be}\) concentration in the sediment sample and the inferred increase in basin-wide denudation rate during the accumulation of the Lima conglomerate thus suggest that changes in hillslope erosion and supply of sediment occurred over a large area. Indeed a localized sediment pulse on a hillside would not be recorded by \textit{in situ} cosmogenic \(^{10}\text{Be}\) in stream sediments.

A second explanation includes the results of changes in uplift patterns. An uplift pulse could have initiated an increase of the erosion rates. However, we consider it unlikely that uplift has to be invoked to explain the formation of the Lima Conglomerate, because a compilation of stratigraphic and sedimentological data together with a geomorphological analysis of the
coastal region of Peru has shown that the region between 6° and 14° latitudes has experienced a long-term phase of subsidence and not uplift (Viveen and Schlunegger, 2018). This sector also includes the region surrounding Lima.

As a third possibility, an eustatic sea level highstand could have lead to the accumulation of the Lima Conglomerate. Indeed, the c. 500 ka period corresponds to a relative sea level highstand. However, we discard the possibility that an eustatic sea level high stand could be the main factor controlling the pulse of sediment. While a sea level rise, and also a highstand could be invoked to explain the construction of an alluvial fan where streams debouch into the sea, such a mechanism is not capable of initiating an erosional pulse in the hinterland.

Possible climate controls on the inferred sediment pulses

Several climate-related mechanisms could be invoked to explain the inferred sediment pulses that are likely to be recorded by the provenance and 10Be signals. In a first model, a shift towards higher precipitation rates has been interpreted as being the main factor controlling the formation of terrace deposits in the Peruvian Andes (Bekaddour et al., 2014; Litty et al., 2017). In a second model, it has been suggested that meltwater surges from the Andean Cordillera during interglacial stades could have caused the accumulation of coarse, reworked glacial moraine material in the Rimac and Chillon fans, thereby forming the Lima Conglomerate (Le Roux et al., 2000). Both models invoke a scenario where a change in the runoff together with a pulse of erosion in the upstream drainage basin resulted in the supply of large volumes of material, thereby controlling the formation of the Lima Conglomerate. The rapid increase in paleo-erosion rates during a short time span indicates that the sediment accumulation possibly corresponded to a pulse of erosion, which is compatible with the proposed two models outlined above. In addition, the contribution of large volumes of glaciogenic material is likely to result in a reduction of the 10Be concentrations in stream sediments, as an analysis in an Alpine drainage basin has shown (Delunel et al., 2014). Moreover, the material of the Lima Conglomerate has been eroded from both the steep middle reaches and the low-relief headwaters (Altiplano) of the Rio Rimac (mainly) and Rio Chillon catchments, while the modern material is mainly derived from the lower steep reaches only (Litty et al., 2017). The provenance results, indicating that the Altiplano represents one of the main sediment sources, are also compatible with the two proposed models. Indeed, the first proposed model infers an increase in the precipitation rates on the Altiplano whereas the second model considers that the meltwater surged from the Andean Cordillera, thereby recycling glaciogenic material. These two mechanisms would lead to an increase of the erosion on the Altiplano and so to an increase of material fluxes with sources on the Altiplano. The paleo-erosion rates and provenance results thus do not allow distinguishing between the two proposed mechanisms.

We then use possible correlations between any known periods of enhanced precipitation or interglacial stades and the obtained accumulation ages to distinguish between the two models of sediment accumulation. The isochron burial age results suggest that the sediment accumulation has been relatively quick. Additionally, the results imply the occurrence of one period of aggradation only, which occurred around 500 ka ago. When considering the orbital and climatic parameters, the 500-ka-old period corresponds to a positive peak in the obliquity angle and to low precession parameters, and also to a time interval of inferred high radiative forcing due to high levels of CO₂ and CH₄, and to a period when the relative temperature was considered to be high (Jouzel et al., 2007). We thus propose that the peaks in the precession parameters and the obliquity have exerted an orbital control on the sediment production. Indeed, on orbital time scales, larger heat contrasts were considered to have shifted the position of the ITCZ, thereby yielding stronger upper-air easterlies and more precipitation on the Altiplano, as recorded by lake level highstands on the plateau (Ouki, Minchin and Taucu pluvial periods, Baker et al., 2001; Fritz et al., 2004). Additionally, the relative high inferred temperatures 500 ka ago are compatible with the model where the meltwater surges during interglacial stades caused a large supply of sediment and thus the formation of the Lima Conglomerate. This study suggests that both models could be invoked to explain the formation of the Lima Conglomerate, and both point towards an orbital control and interglacial meltwater surges on the erosion pulse and the sediment production.

We acknowledge, though, that the inferred interglacial period at 500 ka was rather weak (MIS 13.1), and that the subsequent even warmer interglacial starting at c. 440 ka (Jouzel et al., 2007) apparently lacks a corresponding sedimentary record. Indeed, we would expect that stronger interglacials should have a larger impact on the erosional history of a catchment and on a sedimentary record than a weaker one. It is possible that the Lima Conglomerate is a composite of different units such as that the locus of deposition has shifted farther north during the subsequent warm period. We discard this interpretation because of the constant ages within the vertical section. Alternatively, it is also possible that warm and wet periods are associated with fluvial downcutting instead of sediment accumulation if the hillside material was already depleted during a previous warm and erosive climate. Indeed, whether a warm, or wet period, is associated with an erosional and sedimentary pulse crucially depends on the thickness of soils and hence the sediment reservoir on the hillslopes in a catchment, and on the magnitude–frequency distribution of precipitation during a particular warm period. Models show that the combination of both variables exerts a strong control on whether wet periods are associated with an erosional pulse and the accumulation of sediment on the valley floor, or with further fluvial dissection (Tucker and Slingerland, 1997; Norton et al., 2016). We lack the quantitative data to fully address these questions. However, MIS 13.1 was apparently preceded by a long period of continuous warming prior to peaking at 500 ka (except for a short colder time interval corresponding to MIS 13.2). The subsequent colder period between MIS 12.4 and 12.2 could have been too dry for the regolith to recover after the inferred erosional pulse during MIS 13.1 As a result, the even warmer period thereafter could have been characterized by thin soils, with the consequences that not enough material was available on the hillslopes to produce large volumes of material upon erosion. This is, of course, pure speculation, but it illustrates that whether warm periods may be recorded by terrace levels and conglomerate accumulation not only depends on a particular climate, but also on the preceding geologic and geomorphic history.

Conclusions: Relevance of the Lima Conglomerate in a Broader Context

We suggest that the Lima Conglomerate, like other fluvial terrace systems in Peru (Bekaddour et al., 2014; Trauerstein et al., 2014; Norton et al., 2016), most likely formed in response to a possibly climate-driven sedimentary pulse, which
was sustained enough in space to be recorded by changes in concentrations of cosmogenic $^{10}$Be. As sediment flux then decreased, the river started to incise into the previously deposited conglomerates and started to recycle this material with support by the strong waves. Field work has shown that the coastline of Peru hosts many conglomerate fragments of unknown ages and provenance. We suggest that further dating of these archives would contribute to an improved understanding of how climate changes have imprinted on the erosional history of the Western Peruvian margin (Reber et al., 2017), mainly because a tectonic driving force particularly along the coastline can be ruled out as this area has been subsiding over geological time scales (Viveen and Schlunegger, 2018). We also suggest that the combination of (i) isochron burial dating of conglomerates with $^{10}$Be and $^{26}$Al, (ii) dating of detrital zircon minerals, and (iii) of estimations of paleo-erosion rates using cosmogenic $^{10}$Be will allow one to quantitatively explore these archives for their ages, material provenance and process rates, which in turn is the basis for a better understanding of how erosion systems have possibly responded to climate and climate changes thereof. Our study thus illustrates the potential of these sedimentary archives for a better understanding of possible linkages between shifts in orbital parameters, and surface response including erosion and material transport (Strecker et al., 2007).

The inferred erosional pulse at Lima was likely to have occurred at the scale of nearly the entire drainage basin, supporting the idea of a large-scale, most likely climate driven control. In this context, the accumulation age of c. 500 ka falls into an orbital cycle (eccentricity). Climate changes, with orbital frequencies of c. 100 ka and multiples thereof, and of 40 ka and 20 ka were also considered to have controlled pulses of erosion, sediment discharge and the accumulation of material by modulating the fluvial runoff on the western Andean margin of Peru: Pativilca at $10^7$–$10^8$ T (Frauenstein et al., 2014; Litty et al., 2018); the Pisco valley at $13^2$–$14^2$ S (Steffen et al., 2009) and the Majes valley at 16°13'5 latitudes (Steffen et al., 2010). Accordingly, the Andean mountain range could be perceived as an ideal laboratory for exploring a climate forcing on surface mass fluxes not only for the present time, but also for the geologic history. While the erosional history in other regions on our planet might primarily record either tectonic (e.g. the Himalayas; Ouimet et al., 2009) or glacial signals (Schlunegger and Norton, 2013), the Peruvian Andes might serve as a better laboratory to investigate changes in precipitation possibly in response to an orbital forcing.
